Figure 1.2: Overview of the pressure versus density relation for the full range of densities relevant for neutron stars. Here the evolution of the pressure is shown against the densities depicted in the bottom vertical axis. Green solid line shows the EoS for matter at $T = 10^6$ K, whereas blue line is for $T = 5 \times 10^6$ K, and black for $T = 10^7$ K. Additionally, the upper vertical axis shows the evolution of the radial coordinate computed for one particular EoS (SLy, see Sect. 1.4) and neutron star configuration (mass of $1.4 M_\odot$). Different shaded vertical regions show the corresponding interior structures of the star. Additionally, some interesting densities are highlighted with dashed red lines and text labels (see Sects. 1.2–1.4).

In thermodynamics, we speak of *state variables* that describe a current state of the matter under a given physical conditions. These include, for example, the density ρ , pressure P , and temperature T of the matter. Equation of state is a thermodynamical equation connecting these states variables together. Often, when focusing on neutron stars, what we mean by EoS is a function connecting the pressure and the density of the matter only, $P(\rho)$.

The dependency on the rest of the variables such as temperature can be often forgotten because the matter is *degenerate*. In contrast to the “normal” matter where a statistical moments such as temperature can be used to describe a large ensemble of particles, the degenerate matter is dominated by quantum mechanical effects of single particles. Because of the immense densities, a free particle in a degenerate matter is actually bounded into a finite volume. Inside this small volume, the energy levels of the particle are restricted to take only a discrete set of values called quantum states, because of the underlying wave-nature of the quantum mechanical description. Hence, a notion of temperature, for example, does not make much sense.

Overview of the EoS for the full range of densities relevant to neutron stars is shown in Fig. 1.2. From here it is easy to see that temperature only plays a role in the very uppermost ~ 10 meters of the stars interiors. Behavior of the matter is also quite well known all the way up to the crust-core interface, after which we start to see larger deviations because of the different EoS models. In the Earthly laboratories we

can probe the matter somewhere close to $10^{14} \text{ g cm}^{-3}$, after which the densities becomes too great for us to handle in.* On the other hand, it is exactly starting from this density range that the bulk of the neutron star just starts. Another curious quirk of Nature is how all of the complicated microphysics gets reduced to simple line segments in the logarithmic scales, also known as polytropic pressure relations. In the following sections, we will focus on deriving these simple relations as it helps us in understanding the underlying physics.

1.2 Atmosphere

Atmosphere of a star is the first and uppermost layer responsible for the emergent radiation. It consists of a thin layer of plasma and ranges from a few millimeters to couple of centimeters in height. In most situations the plasma is in a gaseous state, but in some more rare cases when the magnetic field is extraordinarily strong and the temperature is low, the plasma can condensate into a liquid or a solid surface. Such condensed surfaces are, however, rare and usually the gaseous description is more than enough.†

Properties of the emergent thermal radiation strongly depend on the chemical composition of the atmosphere. In the atmospheres of normal stars the composition is a mixture of multiple elements. The most stable chemical element on the surface of a neutron star is iron. However, even a small accreted mass of $10^{-17} M_{\odot}$, originating from the surrounding interstellar medium, is enough to cover the whole star, and hence a variety of elements are also expected in the neutron star atmospheres. On the other hand, the enormous gravity results in an effective separation of elements leading to a strong sedimentation of the atmosphere where the lighter elements are expected to lay on top of the heavier ones.‡ Hence, the atmosphere is usually expected to consist of mainly hydrogen.

1.2.1 General relativistic effects

The effects from the gravity can be quantified by considering a so-called compactness parameter

$$u = \frac{R_S}{R} \quad (1.1)$$

where R is the radius of the neutron star and the corresponding Schwarzschild radius is defined as

$$R_S = \frac{2GM}{c^2} \approx 2.95 \frac{M}{M_{\odot}} \text{ km}, \quad (1.2)$$

where G is the gravitational constant, c is the speed of light, and M is the mass of the star. Hence, a neutrons star has a compactness parameter in the range of $u \approx 1/5$ to $1/2$ resulting in a considerable general relativistic corrections. In comparison, the Sun has $u \approx 4.24 \times 10^{-6}$. Gravitational acceleration under general relativistic theory is

$$g = \frac{GM}{R^2} \frac{1}{\sqrt{1-u}} = 1.38 \times 10^{14} \frac{1}{\sqrt{1-u}} \left(\frac{M}{M_{\odot}} \right) \left(\frac{10 \text{ km}}{R} \right)^2 \text{ cm s}^{-2}. \quad (1.3)$$

Hence, a surface gravitational accelerations g of $\sim 10^{14}$ to $\sim 10^{15} \text{ cm s}^{-2}$ are expected for neutron stars. By considering a barometric atmosphere we can also estimate the scale height as

$$H_a = \frac{k_B T}{m_i g} \approx \frac{0.83}{A} \left(\frac{T}{10^6 \text{ K}} \right) \left(\frac{10^{14} \text{ cm s}^{-2}}{g} \right) \text{ cm} \quad (1.4)$$

*Maximum densities reached in the Earth are usually obtained by colliding heavy nucleons together, momentarily creating a core of even denser matter. The densest naturally occurring element found on top of planet Earth is osmium that has a density of

“just” $\rho \approx 2.2 \times 10^4 \text{ g cm}^{-3}$.

†for a review, see [1] V. E. Zavlin and G. G. Pavlov. 2002;

[2] A. Y. Potekhin. *Physics Uspekhi*. (2014).

‡ [3] C. Alcock and A. Illarionov. *ApJ*. (1980).

where $k_B = 1.38 \times 10^{-16}$ erg K⁻¹ is the Boltzmann constant, T is the temperature of the atmosphere, $m_i = Am_u$, and $m_u \approx 1.66 \times 10^{-24}$ g is the atomic mass unit. From here, the typical scale height values of ~ 1 cm to ~ 10 cm are re-obtained for atmospheres of $T = 10^6$ and 10^7 K.* Strong gravitational field also bends the photon trajectories.† Hence, in addition to the radius R of the star as measured in the local reference frame, another *apparent* radius, as measured by an observer at infinity,

$$R_\infty = \frac{R}{\sqrt{1-u}}, \quad (1.5)$$

is usually needed when describing the observable features of the atmosphere. From here it is then clear that the atmosphere and the emerging radiation encodes information from the physical parameters of the star. More specifically information about the temperature, surface gravity, chemical composition, compactness can be obtained.

1.2.2 Basic equations of the atmosphere

The standard approach in describing the atmosphere structure includes solving three main equations of radiative transfer, hydrostatic balance, and energy conservation. First such a low- B field model of neutron star atmospheres were presented in the pioneering work by Romani.‡ Let us next see, walk through these equations, as they are rather simple. A more general description for the atmosphere model computations are given in Sect.XX§, where the full relativistic electron scattering is also taken into account.

Because the thickness of the atmosphere is much smaller than the radius of the star,¶ the atmosphere can be considered in plane-parallel approximation. Rather high densities, on the other hand, allow to consider the plasma of the atmosphere in local thermodynamical equilibrium.

Spectrum, beaming and polarization of emerging radiation can be determined from radiation transfer problem in atmospheric layers. Radiation can be understood as an energy flow, i.e., energy E per area A , time t , frequency ν , and solid angle Ω . This is known as the specific spectral intensity which we can mathematically formulate as

$$I_\nu = \frac{dE}{dAdtd\nu d\Omega}. \quad (1.6)$$

Radiation averaged over the solid angle, or the so-called mean specific intensity (zeroth moment of I_ν) is then

$$J_\nu = \frac{1}{4\pi} \int_\Omega I_\nu d\Omega = \frac{1}{4\pi} \int_0^{2\pi} \int_0^\pi I_\nu \sin\theta d\theta d\phi = \frac{1}{2} \int_{-1}^{+1} I_\nu d\mu, \quad (1.7)$$

where we have assumed that the radiation does not depend on the azimuthal ϕ angle (as is typical for atmosphere calculations) and introduced $\mu = \cos\theta$. Net rate of energy flowing across an unit area (for example a photon detector) from *all directions* per time and frequency is known as physical flux.‖ It is proportional to the first-order moment of I_ν and is defined as

$$F_\nu = 2\pi \int_{-1}^{+1} I_\nu \mu d\mu. \quad (1.8)$$

* [1] V. E. Zavlin and G. G. Pavlov. 2002; [2] A. Y. Potekhin. *Physics Uspekhi*. (2014).

† [4] K. R. Pechenick, C. Ftaclas, and J. M. Cohen. *ApJ*. (1983).

‡ [5] R. W. Romani. *ApJ*. (1987).

§NKS15.

¶Recall the scale height of 1 to 10 cm in comparison to the radius of 10^6 cm.

‖Strictly speaking, the first-order moment of I_ν is known as the Eddington flux $H_\nu = \frac{1}{2} \int_{-1}^{+1} I_\nu \mu d\mu$. Physical flux is related to it as $F_\nu = 4\pi H_\nu$ and sometimes one also encounters the “astro-physical” flux defined as F_ν/π .

Similarly, the second-order moment of I_ν , or a so-called K-integral, is

$$K_\nu = \frac{1}{2} \int_{-1}^{+1} I_\nu \mu^2 d\mu, \quad (1.9)$$

which is related to the radiation pressure, as we later on will see.

Now we can introduce the radiative transfer equation for I_ν as

$$\mu \frac{dI_\nu}{d\tau} = \frac{\mu}{\kappa_\nu} \frac{dI_\nu}{dy} = -\frac{\mu}{\rho \kappa_\nu} \frac{dI_\nu}{dz} = I_\nu - S_\nu \quad (1.10)$$

where τ is the optical depth, y is the column density (mass per area), z is the horizontal distance from the surface, $\kappa_\nu = \alpha_\nu + \sigma_\nu$ is the total radiative opacity including contributions from the “true” opacity α_ν and from the scattering opacity σ_ν . Here the connection between different independent variables is given as

$$d\tau = \kappa_\nu dy = -\kappa_\nu \rho dz, \quad (1.11)$$

relating the optical depth (distance as experienced by the radiation), column density (projected number density of matter along the path of the radiation), and the horizontal height. In addition we need the source function

$$S_\nu = (\sigma_\nu J_\nu + \alpha B_\nu) \kappa_\nu^{-1}, \quad (1.12)$$

where the scattering term is proportional to the mean spectral intensity J_ν and the “true” absorption term to the thermal Planck function

$$B_\nu(T) = \frac{2h\nu^3}{c^2} \frac{1}{\exp[h\nu/(k_B T)] - 1}, \quad (1.13)$$

where $h = 6.63 \times 10^{-27}$ erg s is the Planck constant. As an boundary conditions for this equation, we can use $I_\nu = 0$ for $\mu < 0$ at $y = 0$ (i.e., the surface). The atmospheres are also usually considered to be in radiative and hydrostatic equilibrium, i.e., (quasi-)stationary. The first requirement can be formulated as

$$\int_0^\infty d\nu \int_{-1}^{+1} I_\nu \mu d\mu = \sigma_{\text{SB}} T_{\text{eff}}, \quad (1.14)$$

where $\sigma_{\text{SB}} = 5.67 \times 10^{-5}$ g s⁻³ K⁻⁴ is the Stefan-Boltzmann constant and T_{eff} is the effective temperature of the atmosphere. The second hydrostatic equilibrium, demands that

$$\frac{dP}{dy} = g - g_{\text{rad}}, \quad (1.15)$$

where, in addition to the gravitational acceleration g we need the opposing radiative acceleration g_{rad} . Finally, we need to supplement these equations with an equation connecting the pressure and density. For the rarefied atmosphere, the ideal gas law is an excellent approximation

$$P = nk_B T, \quad (1.16)$$

where n is the number density of particles.

1.2.3 Eddington limit

Usually the atmospheres we calculate are dynamically stable and in hydrostatic balance because large gravity implies $g_{\text{rad}} \ll g$. Sometimes, however, the radiation flux might increase to such a strength that it is able to compete against even the enormous gravity of a neutron star. An important limit can then be defined for $g_{\text{rad}} = g$, known as the Eddington limit after a renowned astrophysicist Sir Arthur Eddington. Let us now for completeness derive this limit.*

We can start by formulating the radiation pressure. This can be easily done when we realize that pressure is just momentum flux, and photons carry a momentum of E/c .[†] In terms of I_ν this is then

$$P_{\text{rad},\nu} = \frac{1}{c} \int_0^{2\pi} \int_{-1}^{+1} I_\nu \mu^2 d\mu = \frac{4\pi}{c} K_\nu, \quad (1.17)$$

relating the pressure and the second-order moment K_ν together. Radiative acceleration is then

$$g_{\text{rad}} = \frac{dP_{\text{rad}}}{dy} = \frac{d}{dy} \int_0^\infty P_{\text{rad},\nu} d\nu = \frac{4\pi}{c} \frac{d}{dy} \int_0^\infty K_\nu d\nu. \quad (1.18)$$

Let us refine this expression by inserting the definition of K_ν and applying the radiative transfer equation (1.10) without the source function S_ν . In the process we also have to take into account that we are only interested in the outgoing flux, hence the integration limits of μ need to be changed as $[-1, +1] \rightarrow [0, +1]$. We can then simplify the (1.18) to

$$\begin{aligned} g_{\text{rad}} &= \frac{4\pi}{c} \frac{d}{dy} \int_0^\infty d\nu \frac{1}{2} \int_0^{+1} I_\nu \mu^2 d\mu \\ &= \frac{2\pi}{c} \int_0^\infty d\nu \int_0^{+1} \mu d\mu \left\{ \mu \frac{d}{dy} I_\nu \right\} \\ &= \frac{2\pi}{c} \int_0^\infty d\nu \int_0^{+1} \mu d\mu \kappa_\nu I_\nu \\ &= \frac{2\pi}{c} \int_0^\infty d\nu \kappa_\nu \int_0^{+1} I_\nu \mu d\mu \\ &= \frac{1}{c} \int_0^\infty \kappa_\nu F_\nu d\nu. \end{aligned} \quad (1.19)$$

From the bottom line of Eq. (1.19) we see that the K-integral is related to the flux of the radiation F_ν . Not every photon, however, interacts and collides with the matter, and hence the opacity correction κ_ν is also needed, representing effectively the fraction of radiation interacting with the matter. If we now integrate over all the frequencies we obtain

$$g_{\text{rad}} = \frac{1}{c} \kappa F \quad (1.20)$$

Setting it equal to g we can solve for the Eddington flux as

$$F_{\text{Edd}} = \frac{gc}{\kappa} \frac{1}{\sqrt{1-u}} = \frac{GMc}{R^2 \kappa} \frac{1}{\sqrt{1-u}}. \quad (1.21)$$

*for a more in depth discussion, see e.g., [6] G. B. Rybicki and A. P. Lightman. 1979; [7] J. Frank, A. King, and D. J. Raine. 2002.

[†]Energy of a photon is $E = h\nu = mc^2$, from which we obtain

the photon rest mass of $h\nu/c^2 = E/c^2$. Momentum, on the other hand, is just velocity times the mass, so for a photon it is $E/c^2 \times c = E/c$.

Usually in many astrophysical scenarios the opacity is dominated by the electron Thomson scattering opacity, $\sigma_T = 6.65 \times 10^{-25} \text{ cm}^2$. Mass for a hydrogen plasma is, on the other hand, mainly set by the protons, hence, opacity per mass is then

$$\kappa \approx \frac{\sigma_T}{m_p}. \quad (1.22)$$

Finally, by calculating the total radiation flux through the stellar surface, we can define a quantity called luminosity as

$$L = 4\pi R^2 F(R), \quad (1.23)$$

where $F(R)$ is the outgoing radiation flux at the surface. Using the aforementioned equation, we can then define the Eddington luminosity for a star as

$$L_{\text{Edd}} = \frac{4\pi G M c m_p}{\sigma_T} \approx 1.3 \times 10^{38} \left(\frac{M}{M_\odot} \right) \text{ erg s}^{-1}. \quad (1.24)$$

For neutron stars close to $T \sim 10^7 \text{ K}$ this limit can be reached, after which the atmosphere is momentarily blown away.

1.3 Crust

Below the gaseous atmosphere, a solidified layer of matter exists, called crust. Between the atmosphere and crust, a liquid ocean of ions also exists, but the interface is not very strict and the matter is smoothly evolving from one state to another. The solidified crust is also typically divided into an outer and inner layers, but the interface is again ambiguous. The pressure here is almost fully given by the degenerate electrons, and hence the matter is familiar already from white dwarfs. In the beginning, the electrons can be taken to be non-relativistic but after about $\rho \sim 10^6 \text{ g cm}^{-3}$ they turn into ultra-relativistic because of the increasing density.

By definition, the outer crust is a layer in the neutron star interiors where the plasma consists of electrons and nuclei, whereas the inner crust is characterized by an additional appearance of neutrons that start to drip out from the extremely neutron-rich nuclei. The density this occurs is called the neutron drip density and is of around $\rho_{\text{ND}} \sim 4 \times 10^{11} \text{ g cm}^{-3}$. The outer crust, when defined to begin from the atmosphere at $\rho \sim 10^3 \text{ g cm}^{-3}$ and continue to about ρ_{ND} is only about some hundred meters in thickness. The characteristics of the matter are strongly dependent on the Coulomb interactions of charged particles that form a solid Coulomb crystal.

The inner crust is taken to continue all the way down to the crust-core interface, where the matter turns liquid again. This layer is about one kilometer thick. Here, at the bottom of the crust, the density is already close to the nuclear density of $\rho_n = 2.8 \times 10^{14} \text{ g cm}^{-3}$ but the exact location of the transition depends on the detailed microphysics of the core. The fraction of free neutrons grows with the increasing density. Because the normal nuclei here are immersed into free neutron gas, the nuclear interactions play a crucial role in defining the matter. Finally, the nuclei disappear totally when we enter the core. Before that, however, the nuclei form complicated structures that evolve together with the density. This region is also known as the nuclear pasta phase, as the different molecular structures are named after the pasta types that they resemble.

1.3.1 Degenerate gas and Fermi momentum

The matter in the crust is degenerate. Let us discuss the physics behind degenerate matter and the related important concept of Fermi energy now. Elementary 6-dimensional phase space cell of any particle is bounded by the Heisenberg uncertainty principle as

$$\Delta x \Delta y \Delta z \Delta p_x \Delta p_y \Delta p_z = h^3, \quad (1.25)$$

where $\Delta x \Delta y \Delta z$ is the volume in ordinary space, $\Delta p_x \Delta p_y \Delta p_z$ the volume in the momentum space, and h is the previously defined Planck constant. In accordance with the quantum mechanics, there is room for only one particle of any kind inside the elementary cell. In general the number density is given as

$$n_{\text{av}} = \frac{g}{\exp[(E - \mu)/k_B T] \pm 1}, \quad (1.26)$$

where $+$ is used for fermions (such as electrons and protons), and $-$ for bosons (such as photons). Additionally, the g is the number of different quantum states a particle may have inside the cell, E is the total particle energy, and μ is the chemical potential explained more carefully later on. Number of particles with momentum between p and $p + dp$ is

$$n(p)dp = n_{\text{av}} \frac{4\pi p^2}{h^3} dp, \quad (1.27)$$

i.e., particles inside a spherical shell with a surface $4\pi p^2$ and thickness dp . Number density of particles with all momenta is then

$$n = \int_0^\infty n(p)dp \quad (1.28)$$

and the density is then simply

$$\rho = nm, \quad (1.29)$$

where m is the mass of the particle. The energy in equation (1.26) is the total energy $E \equiv E_{\text{tot}} = E_0 + E_k$, composed of the rest-mass energy $E_0 = mc^2$ and kinetic energy E_k . In special relativity, there exists a relation for the total energy as $E_{\text{tot}}^2 = (mc^2)^2 + (pc)^2$, so

$$E = mc^2 \left[1 + \left(\frac{p}{mc} \right)^2 \right]^{1/2}, \quad (1.30)$$

and the kinetic energy is then simply

$$E_k = mc^2 \left[\left(1 + \left(\frac{p}{mc} \right)^2 \right)^{1/2} - 1 \right]. \quad (1.31)$$

Simple asymptotic limits can be obtained for the kinetic energy as

$$E \approx \frac{p^2}{2m} \quad p \ll mc \text{ (non-relativistic case)} \quad (1.32)$$

and

$$E \approx pc \quad p \gg mc \text{ (ultra-relativistic case)}. \quad (1.33)$$

Let us now focus on fermions only, and hence select the $+$ -sign (Fermi-Dirac distribution) from the Eq. (1.26). Fermions are spin $\frac{1}{2}$ particles so we can also set $g = 2$. The chemical potential μ in Eq. (1.26) is expressed as

$$\mu = mc^2 + \epsilon_F \quad (1.34)$$

where ϵ_F is now the so-called Fermi energy. On the other hand, it can also be defined as

$$E - \mu = E_k - \epsilon_F \quad (1.35)$$

i.e., difference between the kinetic and Fermi energy. Hence, the number density of fermions in general is

$$n_f = \frac{8\pi}{h^3} \int_0^\infty \frac{p^2 dp}{\exp(\frac{E_k - \epsilon_F}{k_B T}) + 1}. \quad (1.36)$$

If Fermi energy $\epsilon_F \ll 0$ the distribution will be Maxwellian even for small kinetic energies. On the other hand, if $\epsilon_F \gg k_B T$ we can divide the integrand of Eq. (1.36) into two distinct regions of

$$n_f = \begin{cases} p^2 & \text{if } E_k \ll \epsilon_F \\ 0 & \text{if } E_k \gg \epsilon_F \end{cases} \quad (1.37)$$

where the transition occurs rather sharply at $E_k = \epsilon_F$. This allows us to define a characteristic momentum related to the transition, called Fermi momentum p_F , so that

$$n_f = \frac{8\pi}{h^3} \int_0^{p_F} p^2 dp = \frac{8\pi}{3} \left(\frac{p_F}{h} \right)^3. \quad (1.38)$$

Physically this can be interpreted such that when the temperature decreases, the fermions start to occupy all the quantum states starting from the one with lowest energy all the way up to the Fermi energy. Because of the Pauli exclusion principle, no more than one fermion can exist in the same quantum state so the levels are filled in order, and all the higher states will remain empty. Hence, the highest momenta possible in the degenerate matter is the Fermi momentum

$$p_F = \left(\frac{3n_f}{8\pi} \right)^{1/3} h. \quad (1.39)$$

1.3.2 Why neutrons then?

Let us first consider an ideal gas of degenerate electron-proton-neutron plasma to understand the basic composition of the crust.* In a degenerate plasma all the quantum states are filled up all the way to the Fermi energy, as we just learned. Normal beta-decay mode for the neutrons, on the other hand, is

$$n \rightarrow p + e^- + \bar{\nu}_e, \quad (1.40)$$

that describes the possible path of how a neutron n will decay into a proton p , electron e^- , and electron neutrino $\bar{\nu}_e$. It is because of this decay, that we do not expect to see any free neutron flying around. Such a decay is, however, might be blocked because there is no room for an emission of an extra electron e^- or a proton p .

Let us then only focus on the decay of the most energetic neutrons with an energy equal to the Fermi energy $\epsilon_F(n)$, where the related particle species is defined inside the parentheses. Co-existence of neutrons, protons, and electrons is then guaranteed (at zero temperature) if

$$\epsilon_F(n) = \epsilon_F(p) + \epsilon_F(e^-). \quad (1.41)$$

Massive neutrons and protons are to a good approximation non-relativistic up to a densities of ρ_n , and hence energy is simply a sum of their rest mass energy and kinetic energy

$$\epsilon_F(n) \approx m_n c^2 + \frac{p_F(n)^2}{2m_n}, \quad (1.42)$$

*see e.g. [8] A. C. Phillips. 1994.

and

$$\epsilon_F(p) \approx m_p c^2 + \frac{p_F(p)^2}{2m_p}. \quad (1.43)$$

Electrons, on the other hand, are already ultra-relativistic, and so

$$\epsilon_F(e^-) \approx p_F(e^-)c^2. \quad (1.44)$$

Also note that $n_p = n_e$, as the star is electrically neutral.

From this we find relation of the $n_n/n_p \sim 1/200$ by taking into account the rest mass difference $m_p - m_n = 2.6 \text{ MeV } c^2$ at $\rho \sim \rho_n$. Thus, we conclude that the matter inside is expected to be neutron rich, even though normally the neutrons would β decay back to protons and electrons. Not only is the pressure then responsible for the degeneracy but it is also the source of the neutron enrichment.

1.3.3 Degenerate electron gas

Here the equation of state is described by the relativistic degenerate electron gas. Physics behind this are quite simple and we repeat the calculations here to give the reader ideas about what are the most important physical processes. The result also bears some historical value.

We have reached densities where the EoS is dominated mainly by the electrons, hence it is characterized by the electron number density n_e and temperature T_e (hereafter just T in this section). Moving on from an ideal plasma, we can start by introducing corrections produced by the closely packed charges. In practice we can use the so-called ion-sphere model to describe our Coulomb liquid of ions. We now assume that our ions are emerged into a sea of rigid electron background that takes care of the charge neutrality. Let us begin by defining a so-called electron sphere radius

$$r_e = \left(\frac{4\pi n_e}{3} \right)^{-1/3} \quad (1.45)$$

We can also parameterize the strength between Coulomb (charge) interactions by considering a ratio of potential energy to the kinetic energy with

$$\Gamma_e = \frac{e^2}{r_e k T}. \quad (1.46)$$

Similarly, for ion with a charge number of Z_i , we can define the ion-sphere radius

$$r_i = r_e Z_i^{1/3} \quad (1.47)$$

that encapsulates enough area to be charge neutral, when considering a static electron-induced background from n_e . Ion Coulomb coupling factor is similarly

$$\Gamma_i = \Gamma_e Z_i^{5/3} = \frac{(Z_i e)^2}{r_i k T} \quad (1.48)$$

In the weak-coupling limit ($\Gamma_i \ll 1$) Debye-Hückel results for the free energy are valid*

$$\frac{F_{\text{ex}}}{V} = \frac{1}{\sqrt{3}} n_i k T \Gamma_i^{3/2} \quad (1.49)$$

* [9] L. D. Landau and E. M. Lifshitz. 1980.

Hence, the pressure correction due to the Coulomb interactions is*

$$P_{\text{ii}} \approx -0.3n_{\text{i}} \frac{Z^2 e^2}{r_{\text{i}}}. \quad (1.50)$$

For a degenerate system it also makes sense to present the Fermi quantities: momentum

$$p_{\text{F}} = \hbar(3\pi^2 n_{\text{e}})^{1/3} \quad (1.51)$$

energy

$$\epsilon_{\text{F}} = c^2 \sqrt{(m_{\text{e}} c)^2 + p_{\text{F}}^2}, \quad (1.52)$$

and temperature

$$T_{\text{F}} = \frac{m_{\text{e}} c^2}{k} \left(\sqrt{1 + \left(\frac{p_{\text{F}}}{m_{\text{e}} c} \right)^2} - 1 \right) = T_{\text{r}}(\gamma_{\text{r}} - 1), \quad (1.53)$$

where we have defined a typical temperature

$$T_{\text{r}} \equiv \frac{m_{\text{e}} c^2}{k} \sim 6 \times 10^9 \text{ K} \quad (1.54)$$

relativistic scaling factor

$$\gamma_{\text{r}} \equiv \sqrt{1 + x_{\text{r}}^2}, \quad (1.55)$$

and typical (dimensionless) momentum

$$x_{\text{r}} \equiv \frac{p_{\text{F}}}{m_{\text{e}} c}. \quad (1.56)$$

Using these definitions, it is easy to characterize our electron gas into regions of

- non-relativistic, for which $T \ll T_{\text{r}}$ and $x_{\text{r}} \ll 1$,
- mildly-relativistic, $T \sim T_{\text{r}}$ and $x_{\text{r}} \sim 1$,
- ultra-relativistic, $T \gg T_{\text{r}}$ and $x_{\text{r}} \gg 1$,
- non-degenerate, $T \gg T_{\text{F}}$,
- mildly degenerate, $T \sim T_{\text{F}}$,
- and strongly degenerate $T \ll T_{\text{F}}$.

Free energy

$$F = (\mu - m_{\text{e}} c^2) n_{\text{e}} - \frac{2}{(2\pi\hbar)^3} \int d\vec{p} \frac{1}{3} \vec{p} \cdot \vec{v} f_{\text{F-D}}(\epsilon) \quad (1.57)$$

where

$$n_{\text{e}} = \frac{2}{(2\pi\hbar)^3} \int d\vec{p} f_{\text{F-D}}(\epsilon), \quad (1.58)$$

* [10] D. R. Dewitt *et al.* *Phys. Rev. A.* (1996).

and

$$f_{\text{F-D}}(\epsilon, T) = \frac{1}{\exp\left(\frac{\epsilon - \mu}{kT}\right) - 1} \quad (1.59)$$

and

$$\epsilon = \sqrt{m_e^2 c^4 + p^2 c^2} \quad (1.60)$$

Pressure

$$P = - \left(\frac{\partial F}{\partial V} \right)_{T, \{N_j\}} \quad (1.61)$$

Sommerfield expand free energy in powers of T/T_F

$$\frac{F}{V} = \frac{m_e c^2}{\lambda_C^3} \frac{1}{8\pi^2} \left(x_r (1 + 2x_r^2) \gamma_r - \ln(x_r + \gamma_r) + \frac{4\pi^2}{9} t_r^2 x_r (\gamma_r + \gamma_r^{-1}) \right) + O(t_r^4) \quad (1.62)$$

and obtain pressure

$$P_{\text{id}}^{(e)} = \frac{P_r}{8\pi^2} \left(x_r (1 + 2x_r^2) \gamma_r - \ln(x_r + \gamma_r) \right) \quad (1.63)$$

where again typical pressure

$$P_r = \frac{m_e c^2}{\lambda_C} \sim 1.4 \times 10^{25} \text{ dyn cm}^{-2} \quad (1.64)$$

Hence, it takes the simple polytropic form

$$P_{\text{id}}^{(e)} \approx \frac{P_r}{9\pi^2 \gamma_{\text{AD}}} x_r^{3\gamma_{\text{AD}}} \quad (1.65)$$

where the polytropic index $\gamma_{\text{AD}} = \frac{5}{3}$ for the non-relativistic $x_r \ll 1$ and $\gamma_{\text{AD}} = \frac{4}{3}$ for the ultra-relativistic case (recall also that $x_r \propto n_e^{1/3}$).

Degenerate electron gas pressure accompanied with the ion Coulomb correction will then actually give us a rather good approximation for the equation of state

$$P(x_r) = P_{\text{id}}^{(e)} + P_{\text{ii}} \quad (1.66)$$

this is valid in a large density range of $10^4 < \rho < 10^{10} \text{ g cm}^{-3}$.

1.3.4 Neutron star pasta

Molecular dynamic simulation

1.4 Liquid core

Outer core. Density ranges $0.5\rho_n < \rho < 2\rho_n$. Several kilometers. Neutrons with several per cent admixture of protons p and electrons e^- . Strongly degenerate. Electrons form almost ideal Fermi gas. Neutrons and protons, interacting via nuclear forces, constitute a strongly interacting Fermi liquid.

Inner core. Where $\rho > 2\rho_n$. Appearance of muon. Central density can be around $(10 - 15)\rho_n$. Very model dependent. Main problem.

Here we consider few (relatively) modern descriptions for the dense matter equation of state. The EoSs can be divided into few different classes based on the particles that they consist of. Here they are divided into matter consisting of

Figure 1.3: Molecular simulation of the crust. Figure adapted from <https://github.com/awsteiner/nstar-plot>.

Figure 1.4: Core EoS.

- plain ($npe\mu$) nuclear matter,
- normal nuclear matter spiced up with hyperons (H),
- normal nuclear matter together with more exotic particles like pion and kaon condensates (πK),
- and matter consisting of (or normal matter spiced up with) quarks (q).

For ($npe\mu$) we include models computed with

- potential method using SLy effective nuclear interaction that is of Skyrme-type,^{*}
- four variational method EoSs, APR3/4[†] and WFF1/2[‡],
- two relativistic Brueckner-Hartree-Fock calculations, ENG[§] and MPA1[¶],
- two relativistic mean-field theory, MS1 and MS1b (same as MS1 but with lower symmetry energy)^{||}.

For hyperon models (H) we include

- one variant of relativistic mean-field theory EoS H4^{**}.

EoSs where mesons, like pion and kaon condensates (πK), are taken into account end up not being stiff enough.

Finally, for the hybrid nuclear matter and quark matter compositions (q) we include

- mixed APR nuclear matter and color-flavor-locked quark matter EoS ALF2.^{††}

1.4.1 Polytropes

Parameterize everything with polytropes.

$P(\rho) = K\rho^\gamma$, γ is a the polytropic index and is a measure of *stiffness* of the EoS. how strongly the matter responds to an increase in density with an increase in pressure

1.5 Tolman-Volkoff-Oppenheimer equations

Newtonian pressure gradient needed to oppose the gravity is

$$\frac{dP}{dr} = -\frac{Gm\rho}{r^2}. \quad (1.67)$$

$$\frac{dm}{dr} = 4\pi r^2 \rho, \quad (1.68)$$

Taking into account the general relativistic corrections we get

$$\frac{dP}{dr} = -\frac{GM\rho}{r^2} \times \frac{(1 + P/\rho c^2)(1 + 4\pi r^3 P/mc^2)}{1 - 2Gm/rc^2}. \quad (1.69)$$

Figure 1.5: Overview of the neutron star structure. Right side of the figure shows a schematic presentation of the star's interiors against the radial coordinate, whereas the left side shows the pressure (blue; bottom axis) and cumulative mass (red; top axis) evolution from the core to the surface.

Difference originates from the source of gravity: in the Newtonian case it is the mass m , whereas in the General relativity it is the energy momentum tensor that depend both on the energy density and the pressure. As a result, energy and pressure give rise to a gravitational fields.

Severness of the GR corrections can be estimated from the so called compactness parameter

$$x = \frac{GM}{Rc^2} \approx 2.95 M / M_{\odot} \text{ km} \quad (1.70)$$

It has an important consequence to the stability of neutron stars: Successive increase in the pressure to counter the gravity is ultimately self-defeating.

Solution for a constant density ρ_0 gives

$$P(r) = G \frac{2\pi}{3} \rho_0^2 (R^2 - r^2) \quad (1.71)$$

whereas the GR gives

$$P(r) = \rho_0^2 c^2 \left[\frac{(1 - u(\frac{r}{R})^2)^{1/2} - (1 - u)^{1/2}}{3(1 - u)^{1/2} - (1 - u(\frac{r}{R})^2)^{1/2}} \right], \quad (1.72)$$

where $u = 2GM/Rc^2$.

Another perspective is shown in Fig. 1.5 that visualizes the dependency of the pressure and cumulative mass of the star against the radial coordinate as measured starting from the core.
